

Technical Appendix

OVERVIEW

The purpose of this appendix is to provide an §1) overview of the analysis, §2) specific additional results, §3) core Python codes for multistate modeling, and §4) SAS codes for the validation analysis. This material is intended as background technical information for readers interested in further background on our analyses on the longevity of Oscar winning actors. In addition, readers are referred to the GitHub resource for more details on multistate modeling (<https://meter1.readthedocs.io/en/latest/installation.html>).

The most complicated sections of the appendix involves the Python codes that involve 8 files that show details for a multistate transition model. Each file includes annotation where possible to embed explanations. In addition, the codes are also colorized to help stay organized. Red tends to denote data cleaning and organizational steps. Green tends to denote analytic steps and strategies. No other special colours are used. These documents represent earlier versions of the coding now available on GitHub.

§1) Overview of the Analysis

Multistate Transition Model for Testing Survival

Figure 1. Footnote

Diagram of multistate transition model using rectangles to depict initial state (Birth), final state (Death), and four intermediate states (Performer, Control, Nominee, Winner). Transitions between states depicted as arrows. Life expectancy expressed in years and estimated from multistate life-table approach.

§2) Specific Additional Results

Table. Additional Predictors of Survival

CHARACTERISTIC		Life-expectancy for Group	Life-expectancy for Referrant	Difference	95% Confidence Interval
Social Status (referent is control)	Winner	81.3	76.2	5.1	3.3 to 7.3
Birth Era (referent is before 1920)	Recent	79.7	73.7	6.0	3.9 to 8.0
Sex (referent is male)	Female	78.3	75.1	3.2	1.0 to 5.5
Race (referent is white)	Non-white ¶	75.5	76.5	-1.0	-5.2 to 3.1
Birth Country (referent is USA)	Non-USA	78.4	76.0	2.4	0.0 to 4.5
Name (referent is unchanged)	Changed	78.8	76.3	2.5	0.6 to 5.7
Film Genre (referent is any other)	Drama	76.5	76.8	-0.3	-2.7 to 1.9

Footnote

* all estimates from Multi-state model

¶ includes asian, black, or other race

Figure: Analysis of Winners Compared to Nominees

Footnote

Forest plot showing multiple sensitivity analyses of absolute increase in life-expectancy for winners in different subgroups. Referent group in all analyses is nominees and all controls excluded. Circles denote estimate and horizontal lines denote 95% confidence interval. Vertical line for null association marked as a 0 year increase in life expectancy. Sample size in each analysis shown as corresponding count of winners. Findings suggest increased life-expectancy for winners compared to nominees.

Figure: Analysis of Nominees compared to Controls

Footnote

Forest plot showing multiple sensitivity analyses of absolute increase in life-expectancy for nominees in different subgroups. Referent group in all analyses is control performers and all winners excluded. Circles denote estimate and horizontal lines denote 95% confidence interval. Vertical line for null association marked as a 0 year increase in life expectancy. Sample size in each analysis shown as corresponding count of winners. Findings suggest no significant increased life-expectancy for nominees compared to controls.

§3) Core Python Codes of Multistate Modeling

The first file is named PreliminaryDataCleanup and is intended to address performers who made more than one transition in a year (for example, first being nominated and first winning in the same year). In such cases, the person is classified by final state. An additional nuance is to computer each person's age at each transition based on the year of birth and year of transition. Keep in mind the coding shows the specific computer path and would need to be tailored for each programmer individually.

The second file is named MultiStateLifeTable and contains the core functions and subroutines. This name must not be changed since the details are called upon in later programs. The core features include creating the number of people at-risk at each transition (denominator) and the number of people making a transition at the corresponding age (numerator). This allows calculating a transition probability at each year (numerator / denominator). This also allows calculating a survivorship vector (membership of each group at each stage). Additional coding relates to transposing the data into a longitudinal format to allow calculation. Additional coding involves censoring individuals at corresponding stage (for example, transitioning from a nominee to a winner). Some final features involving exporting data for plotting and other analyses.

The third file is named WinnerVsNonWinnerMSM and contains much of the comparative analyses to contrast different groups. This name must not be changed because the details are called for later programs. The core features include using functions from the MultiStateLifeTable file to compare winners to non-winners. Incidentally, the group of non-winners can also be decomposed into the group of nominees and group of controls. This also introduces the bootstrap coding for calculating 95% confidence intervals around estimates. An additional set of codes is provided to compare conventional Kaplan-Meier analyses (no accounting for immortal time bias) to Multi-State analyses (accounting for immortal time bias).

The fourth file is named KaplaMeierDataOutput and contains the codes for creating the figure displaying survival over time in different groups. The core features begin by repairing 3 anomalous performers marked by posthumous nominations or posthumous wins (eg, Heath Ledger). Additional codes create survival probabilities at each year of life for controls, nominees, and winners. The functions used here are based on MultiStateLifeTable file.

The fifth file is named `LifeExpectancyPredictors` and contains the codes for examining additional predictors of survival (for example, sex and race). The main strategy is to calculate life-expectancy by subgroup analyses. The core subgroups are derived from the six baseline characteristics. Specifically, Birth Era (binary), Sex (binary), Race (binary), Country of Birth (binary), Name change (binary), and Drama film genre (binary). The general strategy remains unchanged based on calculating the number of performers at-risk (denominator) and number of transitions (numerator). The coding also again repairs the 3 anomalous performers marked by posthumous nominations or posthumous wins.

The sixth file is named `StratifiedAnalysesWithWinners` and contains codes that enable testing the survival of winners compared to other performers. The core features include the Multi-State estimates of life-expectancies by concentrating on Winners and Controls (the group of Nominees is also included for completeness). The life-expectancy difference between Winners and Controls is calculated along with 95% confidence intervals. This difference is then subjected to secondary analyses based on stratification according to seven features. Specifically, Birth Era (binary), Sex (binary), Race (binary), Multiplicity (binary based on single win vs multiple wins), Age at first win (binary based age 40 years), and Role (binary based on lead vs supporting), and Other Recognitions (binary based on single nomination vs multiple nominations).

The seventh file is named `StratifiedAnalysesNoWinners` and contains codes for testing the survival of nominees and control performers after excluding winners. In essence, performers were included until the year of nomination and were subsequently censored if they won at any time thereafter. These results are not presented in the main manuscript and are intended as an exploratory analysis to further examine the contrast between nominees and winners. The actual analyses and layout mirrors the `StratifiedAnalysesWithWinners` file.

The final file is named `SuperSubgroupAnalyses` and contains codes for examining combination demographic subgroups distinguishing Birth era (binary), Sex (binary), Race (binary). This amounts to eight specific detailed stratified analyses (2 x 2 x 2). The core features rely on the `MultiStateLifeTable` file to evaluate the life-expectancy of winners, nominees, and controls in each group along with bootstrap simulation for all 95% confidence intervals. Each analysis

handles the demographic factor as a static characteristic and again estimates transition probabilities, a survival vector, and life-expectancy.

```
### This script takes the data in the original format (transitions for
individual subjects recorded as calendar years)
### and adds additional rows to the dataset. For each performer we add 10
additional entries. For each of the 5 transitions
### excluding birth we record whether a performer ever made such a
transition (recorded as 1 or 0) and if so, the age
### at which the transition was made. Located here is also our method for
dealing with multiple transitions in a given
### year. If a performer makes more than 1 transition in a given year
then the final transition supercedes. This is to
### say that if I transition from Performer -> Winner -> Death in one
year then I am recorded as transitioning directly from
### nomination to death and my status as a winner is irrelevant.

### This script provides all of the basic functions necessary for Multi-
State Life Tables. The critical functions are:
### atrisk_and_transitions, transitionprobs_and_samplesizes,
survivorship_vector, and life_expectancy. atrisk_and_transitions
### records the risk sets at every given age, which corresponds to the
number of people in each of the states at every given age.
### It also records the number of performers who transition from any
given state to any other state at a given age.
### transitionprobs_and_samplesizes uses the output of this function to
compute the transition probabilities at every age
### and also records the associated sample sizes. survivorship_vector
takes a radix, a vector representing the initial
### distribution of individuals over states to make predictions for, and
an initial age, and outputs the expected
### evolution of that set of individuals over time.

def allowed_transitions(states):

### This script, using many of the basic functions from
MultiStateLifeTable, runs the analysis for winners vs non-winners.
### Essentially, it uses two versions of the dataset: the full dataset
and the dataset with winners censored at date of award.
### In order to run the analysis in stages, unlike MultiStateLifeTable,
it has functionality for specifying which specific
### states to use in the model (as an input to the functions
bootstrap_life_ex2 and KMvsMS). It also contains a basic function
### for computing allowable transitions in a given model based on which
states are included.

§4) SAS Codes for Validation Analysis

The attached document contains the single file with SAS codes using the proportional hazards model as a test of robustness. These models included a time-dependent step-function to account for age at first film, age at study enrolment, age at first nomination, and age at first win.
